We report the detection of single electrons using a Nb_{0.7}Ti_{0.3}N superconducting wire deposited on an oxidized silicon substrate. While it is known that this device is sensitive to single photons, we show that it also detects single electrons with kilo-electron-volt energy emitted from the cathode of a scanning electron microscope with an efficiency approaching unity. The electron and photon detection efficiency map of the same device are in good agreement. We also observe detection events outside the active area of the device, which we attribute to sensitivity to backscattered electrons. © 2010 American Institute of Physics. [doi:10.1063/1.3506692]

The versatility of superconducting nanowires as single particle detectors relies on their sensitivity to the minute amount of energy required to locally induce a resistive transition. From this point of view, the latest achievements involving the detection of organic molecules¹ and photons in the infrared range² all derive from early experiments with α -particles in the million electron volt range.³ In order to go beyond the optical resolution limit, the scanning electron microscope (SEM) working at low temperature,⁴ proved useful. This technique enabled the visualization of the real size of the hot spot caused by a detection process.⁵ However, the best achieved spatial resolution is limited by thermal diffusion to about 1 μm and single electron detection has not been demonstrated. In this paper, we show single electron detection using a superconducting nanowire. Our superconducting single electron detector (SSED) offers a high spatial and timing resolution and we compare the electron detection efficiency map with a photon detection efficiency map, measured on the same device.

The fabrication process of our superconducting nanowire has been described before.⁶ It consists of a 100 nm wide, 500 μm long, and 6 nm thick wire of Nb_{0.7}Ti_{0.3}N. The wire is folded into an $10 \times 10 \mu\text{m}^2$ area, with a separation of 100 nm between adjacent detecting branches. One end of the wire is grounded whereas the other end is connected to a cryogenic coaxial cable used to inject a current through the structure. We measure a dc critical current $I_c = 10 \mu\text{A}$ at 4.2 K and $I_c = 5.2 \mu\text{A}$ at 8 K. Our experimental setup consists of a cryogenic SEM.⁷ The detector is mounted on a cold translation stage at $T = 8$ K under the electronic beam of an SEM. The SEM current I_b is controlled and can be measured with a picoammeter (measurement uncertainty 10%). The energy of the incident electrons E_e can be varied between 5 and 30 keV.

To block low frequency $1/f$ noise we use a dc-block, through which we can only bias the wire with pulses of current amplitude I and duration $t_d = 800$ ns (see inset of Fig. 1). Each pulse is reflected by the circuit. When the current is on,

the detection of an electron triggers a short pulse at the output of the system (duration of a few nanoseconds, see inset of Fig. 1). The change in baseline is caused by the limited bandwidth (0.1 to 1000 MHz) of the amplification of the output pulses but does not affect the bias current of the SSED. We count the average number of detection pulses and compare it to the average incoming number of electrons $n_i = I_b \times t_d / e$ in order to infer the absolute detection efficiency η . We can adjust the current I_b down to a few picoamperes, and obtain single electrons separated by approximately 100 ns. We have measured the number of detection events n_d versus incoming electrons n_i (Fig. 1). The linearity of this plot shows that we detect single electrons. A complete map of η is obtained by scanning the electron beam over the sample with a full control of the step size and dwell time.

To compare the relative performances of our superconducting nanowire detector for single electrons and single photons, we present in Fig. 2(a) a two-dimensional (2D) plot of the photon detection efficiency for our sample, obtained by scanning a laser spot (1 μm diameter) over the detector with an intensity, low enough to be in the single photon

FIG. 1. (Color online) Average number of counted peaks per bias current pulse n_d as a function of the number of incoming electrons $n_i = I_b \times t_d / e$ ($E_e = 10$ keV, $I/I_c = 0.85$). A linear fit (solid line) gives a detection efficiency $\eta = 0.91(0.01)$. (Inset) A typical experimental signal at the output of the detection chain. One pulse corresponds to the detection of one electron.

FIG. 2. (Color online) 2D plots of the detection efficiency. (a), for single photons ($\lambda=532$ nm, $I/I_c=0.8$, step size ~ 100 nm). The white area corresponds to missing data (b), for single electrons (bias current $I/I_c=0.35$, electron energy $E_e=30$ keV, SEM step size 200 nm). (c), same map as (b) with $I/I_c=0.85$, $E_e=20$ keV and SEM step size 200 nm. (d) Zoom of (c) for a $1 \times 1 \mu\text{m}^2$ area, with SEM step size of 20 nm. A square shown in (c) indicates the relative scale and orientation of (d).

regime. A detailed description of the setup is given in Ref. 8. The map shows spatial variations over the active area that could originate from structural and/or chemical inhomogeneities of the layer. This reference image can be compared to Fig. 2(b) which shows the detection efficiency for electrons of energy 30 keV and a detector bias current $I/I_c=0.35$. We observe that the electron detection efficiency is more homogeneous than in the case of photon detection. There exists however a clear correlation between the two measurements, with the maxima and minima located at the same positions for both images. It demonstrates that the detection process is affected in the same way for both particles. It shows also that SEM measurements could be used to characterize the performances of superconducting nanowires for photon detection. With increasing bias current, the electron detection efficiency saturates and becomes homogeneous over the whole detector active area as illustrated by Fig. 2(c) ($I/I_c=0.85$, $E_e=20$ keV). We note that we have also been able to produce electron detection efficiency maps with NbN wires of 500 and 1000 nm widths.⁷ However, the present NbTiN detector covers a larger area and offers a better efficiency with fewer inhomogeneities.

In both Figs. 2(b) and 2(c), one observes sharper details than in Fig. 2(a). This is expected as electron microscopy has a much better spatial resolution than optical microscopy. In order to evaluate our spatial resolution, we present in Fig. 2(d) a $1 \times 1 \mu\text{m}^2$ image of the detection efficiency taken in the conditions of Fig. 2(c). The plot directions make an angle of 60° with respect to the wire direction. It reveals the inner structure of the detector via a small modulation of the detection efficiency (0.05 modulation, compared to an average efficiency of 0.85). The period of the modulation corresponds to the pitch of the meander structure and the visibility of this modulation indicates a spatial resolution of less than 100 nm. We also observed that for electron energies $E_e \leq 10$ keV, the spatial resolution is degraded (to about 850 nm full width at half maximum) and one can no longer dis-

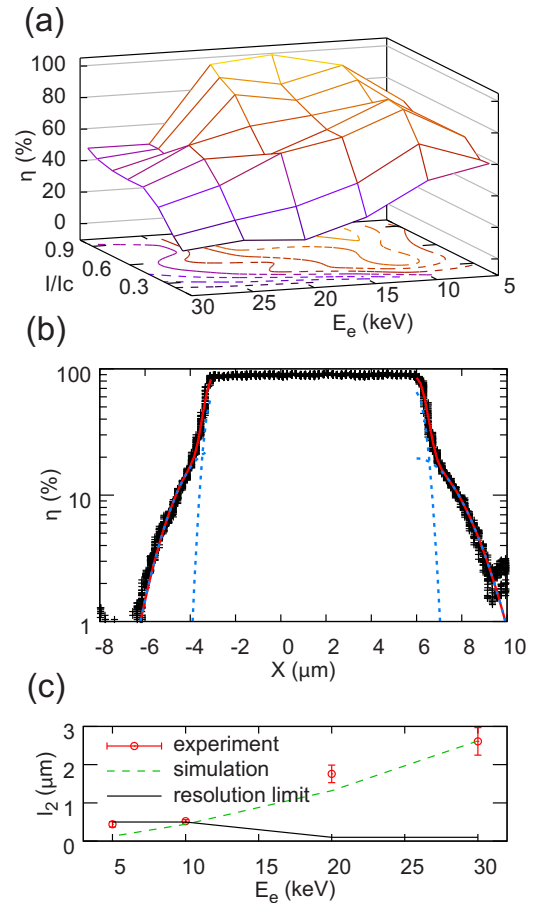

FIG. 3. (Color online) (a) Electron detection efficiency for different values of bias current and electron energy. The beam position is fixed and close to the center of the active area. (b) Cross-section of the detection efficiency map of Fig. 2(c) (log scale). The fall in detectivity at the edge of the active area is fitted by a double Gaussian (dotted lines: individual Gaussians, solid line: sum) with characteristic lengths $l_1=330$ nm and $l_2=1760$ nm, respectively. (c) Plot of l_2 as a function of the electron energy E_e . At high energy (≥ 10 keV), it is in good agreement with Monte Carlo simulations of the mean radius of exit for backscattered electrons, done in Ref. 12.

tinguish individual wires. We attribute this loss of performance to charging effects on the substrate which degrade the SEM spatial resolution.

Figure 3(a) summarizes our results for η as a function of I/I_c and E_e . It shows that η increases with increasing I/I_c and decreases with increasing electron energy. This fact is in good agreement with previous studies that showed that the mean electron energy loss ΔE_e is of the order or 100 eV for the impinging electron energy range we have explored.⁹ Moreover, one has $\Delta E_e = S \times \lambda_{in}$, where λ_{in} is the inelastic mean free path of the electron and S is the stopping power of the material, which is well described by the Bethe formula¹⁰ or empirical variations of the latter.^{9,11} To a first approximation $S=f(E_e)/E_e$ and $\lambda_{in}=g(E_e) \times E_e$ where f and g are slowly varying functions. As a consequence, the first inelastic collision in the detector happens deeper for high energy electrons and is less likely to trigger a transition of the nanowire, explaining the decrease in η with increasing E_e . The low efficiency at $E_e=5$ keV (60%) is not consistent with this model. Our hypothesis is that it arises from trapped charges in the vicinity of the detector (i.e., in a dielectric or nonconductive material) close to the SSED that are also responsible for the degradation of the spatial resolution of the 2D-plots at this energy.

Evidence of the detection of backscattered electrons is provided by the cross-section of the efficiency map of Fig. 2(c), presented in Fig. 3(b). We observe shoulders for the detection efficiency signal at the detector edges, proving that it is still possible to detect electrons impinging at distances larger than the SEM spatial resolution. A double Gaussian fit at the edge for different cross-sections, both horizontal and vertical, gives two average characteristic lengths $l_1 = 330(40)$ nm and $l_2 = 1760(230)$ nm, with a ratio in amplitude around 80:20. We attribute the first length to the finite step size of the SEM beam for this experiment. We attribute the second length scale to the detection of backscattered electrons. This distance is consistent with Monte Carlo simulations of the electron trajectories that predict a mean distance between the entry and exit points of $l_{MC} = 1320$ nm. This distance depends strongly on the energy of the incident electron. We present in Fig. 3(c) a comparison of l_2 and l_{MC} for different values of E_e . At low energy, the distance l_{MC} is of the order of or lower than the apparatus spatial resolution degraded to 500 nm. We only observe a single Gaussian. At larger energies, above 10 keV, the agreement between experiment and simulation is very good.¹²

In conclusion, we have operated a fast and efficient single electron counter using a superconducting nanowire. We show an efficiency close to unity. Its low noise, short dead time, and high timing accuracy make this device interesting in situations where a cryogenic environment is available. Optimizing further these devices for the specific purpose of electron detection can certainly improve future performances. For example, a thin conducting layer on top of the nanowire can reduce the charging effect and improve the efficiency for low energy electrons (≤ 5 keV). For high energy electrons, increasing the superconducting layer thickness will improve the performances. Fabricating the devices over a thin membrane would avoid backscattering. Arrays of such devices, could provide an imaging system for electrons with a time resolution below 60 ps¹³ and a pixel size below 10 μm . Those figures could significantly improve the tech-

nologies presently used for example in ultrafast electron microscopy.¹⁴
